#### **REPETITION STRUCTURES\***

\* Some of the contents are adopted from MATLAB® for Engineers, Holly Moore, 3rd Ed., Pearson Inc., 2012.

#### Repetition Structures

- Usually, sections of computer code can be categorized as sequences, selection structures, and repetition structures.
- As a rule of thumb, if a section of code is repeated more than three times, it is a good candidate for a repetition structure.
  - Why do we need loops?
    - Write on the screen 1000 times

```
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
I am a clown, but I am not funny.
```

#### Repetition Structures, ctd.

#### One way of doing this:

```
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
disp('I am a clown, but I am not funny.');
•••
disp('I am a clown, but I am not funny.');
```

### Repetition Structures, ctd.

- Repetition structures are often called loops. All loops consist of five basic parts.
  - A parameter to be used in determining whether or not to end the loop.
  - Initialization of this parameter.
  - A way to change the parameter each time through the loop. (If you don't change it, the loop will never stop executing.)
  - A comparison, using the parameter, to a criterion used to decide when to end the loop.
  - Calculations to do inside the loop.
     Loops
     while
     for
     continue
     break

#### Repetition Structures, ctd.

- MATLAB supports two different types of loops: the for loop and the while loop.
- Two additional commands, break and continue, can be used to create a third type of loop, called a midpoint break loop.
- The for loop is the easiest choice when you know how many times you need to repeat the loop.
- While loops are the easiest choice when you need to keep repeating the instructions until a criterion is met.
- Midpoint break loops are useful for situations where the commands in the loop must be executed at least once, but where the decision to exit the loop is based on some criterion

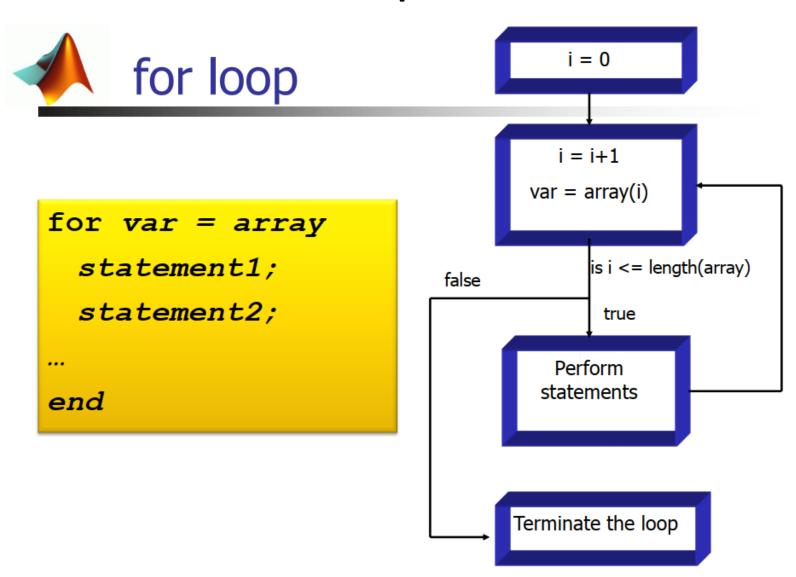

#### for Loops

- The structure of the for loop is simple. The first line identifies the loop and defines an index, which is a number that changes on each pass through the loop and is used to determine when to end the repetitions.
- After the identification line comes the group of commands we want to execute.
- Finally, the end of the loop is identified by the command end.
- Thus, the structure of a for loop can be summarized as

```
for index = [matrix]
     commands to be executed
end
```

 The loop is executed once for each element of the index matrix identified in the first line. Here's a simple example:

for 
$$k = [1, 3, 7]$$
  
k  
end

- The index in this case is k. Programmers often use k as an index variable.
- The index matrix can also be defined with the colon operator or, indeed, in a number of other ways as well.
- Here's an example of code that finds the value of 5 raised to powers between 1 and 3:

for 
$$k = 1:3$$
  
  $a = 5^k$ 

- On the first line, the index, k, is defined as the matrix [1, 2, 3].
- The first time through the loop, k is assigned a value of 1, and 5<sup>3</sup> is calculated.
- Then the loop repeats, but now k is equal to 2 and 5<sup>2</sup> is calculated.
- The last time through the loop, k is equal to 3 and 5^3 is calculated.

```
a = 5
a = 25
a = 125
```

```
for k = 1:5
 a(k) = k^2
end
```

 This loop defines a new matrix, a, one element at a time. Since the program repeats its set of instructions five times, a new element is added to the a matrix each time through the loop, with the following output in the command

 Most computer programs do not have MATLAB's ability to handle matrices so easily; therefore, they rely on loops similar to the one just presented to define arrays. It would be easier to create the vector a in MATLAB with the code

$$k = 1:5$$
 $a = k.^2$ 

#### which returns

This is an example of vectorizing the code.

 Another common use for a for loop is to combine it with an if statement and determine how many times something is true. For example, in the list of test scores shown in the first line, how many are above 90?

```
scores = [76,45,98,97];
count = 0;

for k=1:length(scores)
  if scores(k)>90
     count = count + 1;
  end
end

disp(count)
```

### for Loops, Example-1

compute the sum of squares of numbers 1 to 10

```
n = 10; sumsq = 0;
for k = 1 : n
   sumsq = sumsq + k ^ 2;
end
disp(sumsq)
```

Tip: use generic symbols rather than hard coded numbers

How do we do this without a loop?

```
>> sum((1:10).^2)
ans =
```

385

# **Nested Loops**

- It is often useful to nest loops inside other loops.
- We can write a code segment to fill the matrix A

```
cols = 5; rows = 5;
for k=1:cols
    for j=1:rows
        a(i,j)=i*j;
    end
end
```

#### for Loops, Example-2

Write a script called large\_elements that takes as input an array named dimensionVector that is a row matrix or a vector which will store the dimensions of a matrix called as A. The script identifies those elements of A, which will be generated by rand() function, that are greater than the sum of their two indexes. For example, if the element A(2,3) is 6, then that element would be identified because 6 is greater than 2 + 3. The output of the script gives the indexes of such elements found in row major order. It is a matrix with exactly two columns. The first column contains the row indexes, while the second column contains the corresponding column indexes. If no such element exists, the script returns an empty array.

## for Loops, Example-2

```
Aclc
clear all
close all
dimensionVector = input('Enter # of rows and columns as an array= ');
A = round(rand(dimensionVector(1,1), dimensionVector(1,2))*10);
[row col] = size(A);
found = [];
for ii = 1:row
    for jj = 1:col
        if A(ii,jj) > ii + jj % if the element > the sum of its indexes
            found = [found; ii jj]; % add a new row to the output matrix
        end
    end
end
found
```

#### while Loops

While loops are similar to for loops. The big difference is the way MATLAB
decides how many times to repeat the loop. While loops continue until some
criterion is met. The format for a while loop is

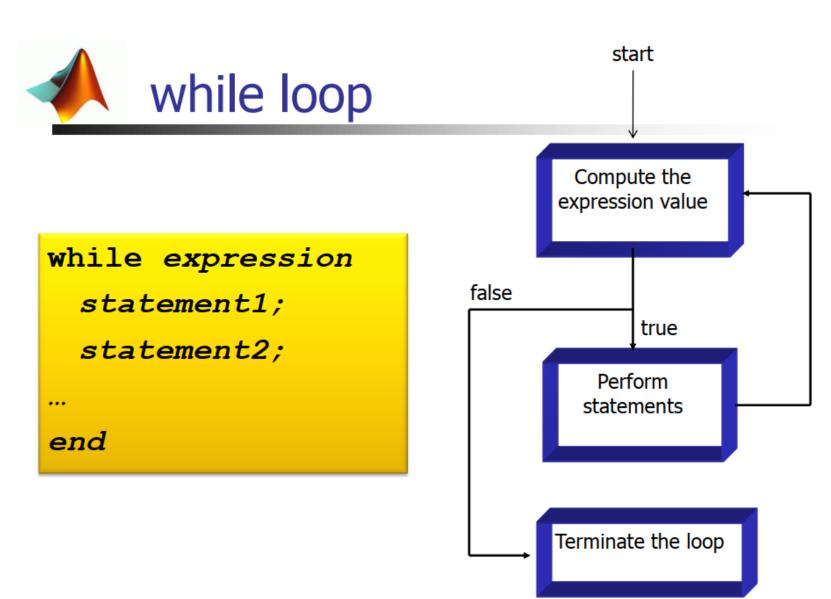

```
while criterion commands to be executed end
```

Here's an example:

$$k = 0;$$
while  $k < 3$ 
 $k = k+1$ 
end

k = 1 k = 2 k = 3

• In this case, we initialized a counter, k, before the loop. Then the loop repeated as long as k was less than 3. We incremented k by 1 every time through the loop, so that the loop repeated three times.

Fall Week #5

• We could also use k as an index number to define a matrix or just as a counter. Most for loops can also be coded as while loops. Recall the for loop in the previous section used to calculate the first three powers of 5. The following while loop accomplishes the same task:

```
k = 0;
while k<3
    k = k+1;
    a(k) = 5^k
end</pre>
```

 Each time through the loop, another element is added to the matrix a, and the code returns

```
a =
5
a =
5 25
a =
5 25 125
Introductory Computer Sciences 2018-2019
Fall Week #5
```

As another example, first initialize a:

$$a = 0;$$

• Then find the first multiple of 3 that is greater than 10:

```
while (a<10)
a = a + 3
end;
```

- The first time through the loop, a is equal to 0, so the comparison is true.
- The next statement ( a = a + 3 ) is executed, and the loop is repeated.
- This time a is equal to 3 and the condition is still true, so execution continues.
- In succession, we have

$$a = 3$$
 $a = 6$ 
 $a = 9$ 
 $a = 12$ 

- while loops can also be used to count how many times a condition is true by incorporating an if statement. Recall the test scores we counted in a for loop earlier.
- We can also count them with a while loop:

```
scores = [76,45,98,97];
count = 0;
k = 0;
while k<length(scores)
    k = k+1;
    if scores(k)>90
        count = count + 1;
    end
end
disp(count)
```

- One common use for a while loop is error checking of user input.
- Consider a program where we prompt the user to input a positive number, and then we calculate the log base 10 of that value.
- We can use a while loop to confirm that the number is positive, and if it is not, to prompt the user to enter an allowed value.
- The program keeps on prompting for a positive value until the user finally enters a valid number.

```
x = input('Enter a positive value of x')
while (x<=0)
    disp('log(x) is not defined for negative numbers')
    x = input('Enter a positive value of x')
end
y = log10(x);
fprintf('The log base 10 of %4.2f is %5.2f \n',x,y)</pre>
```

### while Loops, Example 1.

Write a program that generates the following output:

```
      1
      2

      1
      2

      1
      2

      1
      2

      3
      4

      1
      2

      3
      4

      5
      6

      1
      2

      3
      4

      5
      6

      7
      8

      1
      2

      3
      4

      5
      6

      7
      8

      9
      1

      1
      2

      3
      4

      5
      6

      7
      8

      9
      10
```

## while Loops, Example 1, cnt.

Solution:

#### while Loops, Example 2.

Write a program that generates the following output:

1	2	3	4	5	6	7	8	9	10
1	2	3	4	5	6	7	8	9	
1	2	3	4	5	6	7	8		
1	2	3	4	5	6	7			
1	2	3	4	5	6				
1	2	3	4	5					
1	2	3	4						
1	2	3							
1	2								
1									

## while Loops, Example 2.

Solution

```
i = 10;
while i > 0
    disp(1 : i);
    i = i - 1;
end
```

#### while Loops, Example 3.

#### What will the following program print?

#### while Loops, Example 4.

- Write a program that the computes factorial n
  - For example if n = 10 then n! = 10 \* 9 \* 8 ... \* 1

```
n = 10; res = 1;
while n > 1
  res = res * n;
  n = n - 1;
end
disp(res);
```

#### break Statement

• The break command can be used to terminate a loop prematurely (while the comparison in the first line is still true). A break statement will cause termination of the smallest enclosing while or for loop. Here's an example:

```
n = 0;
while (n<10)
    n = n+1;
    a = input('Enter a value greater than 0:');
    if(a \le 0)
        disp('You must enter a positive number')
        disp('This program will terminate')
        break
    end
    disp('The natural log of that number is')
    disp(log(a))
end
```

#### continue Statement

 The continue command is similar to break; however, instead of terminating the loop, the program just skips to the next pass

```
n = 0;
while (n<10)
    n = n+1;
    a = input('Enter a value greater than 0:');
    if(a \le 0)
        disp('You must enter a positive number')
        disp('Enter a value again')
        continue
    end
    disp('The natural log of that number is')
    disp(log(a))
end
```

#### break - continue

 In selection and repetition statements, break and continue is used to alter the flow of control.

```
for count = 1:10
                                           for count = 1:10
% loop 10 times
                                           % loop 10 times
    if (count == 5)
                                               if (count == 5)
         break; % break loop if x is 5
                                                    continue;
    end
                                                    % skip remaining code in loop,
    fprintf("%d ", count);}
                                                    % continue looping
end
                                               end
8 1 2 3 4
                                               fprintf("%d ", count);
                                           end
```

When the compiler encounters break statement, it immediately goes out of the loop

When the compiler encounters continue statement, it immediately stops the execution of that iteration of the loop

% 1 2 3 4 6 7 8 9 10

## Additional Examples 1

Write a matlab script, **approximate\_pi**, that uses the following approximation of  $\pi$ 

$$\pi = \sqrt{12} \sum_{k=0}^{\infty} \frac{(-3)^{-k}}{2k+1}$$

Instead of going to infinity, the script stops at the smallest  $\mathbf{k}$  for which the approximation differs from  $\mathbf{pi}$  (i.e., the value returned MATLAB's built-in function) by no more than the positive scalar, **delta**, which is the only input argument. The first output of the function is the approximate value of  $\pi$ , while the second is  $\mathbf{k}$ . (Note: if your program or the grader takes a long time, you may have created an infinite loop and need to hit Ctrl-C on your keyboard.)

#### ...Example 1...

```
clc
clear all
close all
delta = input('Please enter delta = ');
k = 0;
f = sqrt(12); % compute sqrt(12) only once
a = f; % the value of a for k == 0
while abs(pi-a) > delta % while we are further away than delta
    k = k + 1; % increment k
    a = a + f*(-3)^{(-k)}/(2*k+1); % add increment to current value of a
end
fprintf('approximate value of pi is %f \n',a)
fprintf('k value is %d \n',k)
```

# Example 2

Write a matlab script, **print\_triangle\_star**, that prints the following shape when the row number is entered as **5** 

#### ...Example 2...

```
clc
clear all
close all
row number = input('Please enter row number = ');
for ii = 1:row number %visits all rows, ii has the row
number information
    for kk = 1:ii % prints the stars, controlled by ii
        fprintf('%c','*'); %prints the * char, %c used
for char variables
    end
    fprintf('\n');%new line
end
```

# Example 3

Write a matlab script, **print\_full\_triangle\_star**, that prints the following shape when the row number is entered as **5** 

#### ...Example 3...

```
clc, clear all, close all
row number = input('Please enter row number = ');
for ii = 1:row number %visits all rows, ii has the row information
    for kk = row number-ii:-1:1 %
       fprintf('%c',' '); %prints space char
    end
    for kk = (2*ii) -1:-1:1 %
       fprintf('%c','*'); %prints star char
    end
    for kk = row number-ii:-1:1 %
       fprintf('%c',' '); %prints space char
    end
    fprintf('\n');%new line
end
```
